

No Blind Mice, Thanks To UF Scientists

University of Florida stem cell scientists reported in January that they have prevented blindness in mice afflicted with a condition similar to one that robs thousands of diabetic Americans of their eyesight each year.

Writing in the *Journal of Clinical Investigation*, researchers describe for the first time the link between a protein known as SDF-1 and retinopathy, a complication of diabetes and the leading cause of blindness in working-age Americans.

Scientists explain how they used a common antibody to block the formation of SDF-1 in the eyeballs of mice with simulated retinopathy, ending the explosive blood vessel growth that characterizes the condition. Researchers effectively silenced SDF-1's signal to activate normally helpful blood stem cells, which become too much of a good thing within the close confines of the eyeball.

"SDF-1 is the main thing that tells blood stem cells where to go," said Edward Scott, an associate professor of molecular genetics at the UF Shands Cancer Center and director of the Program in Stem Cell Biology and Regenerative Medicine at UF's College of Medicine. "If you get a cut, the body makes SDF-1 at the injury site and the repair cells sniff it out. The concentration of SDF-1 is higher where the cut occurs and it quickly dissipates.

But the eye is such a

unique place, you've got this bag of jelly — the vitreous — that just sits there and it fills up with SDF-1. The SDF-1 doesn't break down. It continues to call the new blood vessels to come that way, causing all the problems."

Diabetic retinopathy causes 12,000 to 24,000 cases of blindness each year, according to the American Diabetes Association.

UF researchers analyzed samples of the vitreous gel taken from the eyeballs of 46 patients undergoing treatment for diabetic eye disease, including 24 patients with retinopathy. They found SDF-1 in each of the patients, with the highest amounts detected in patients with the worst cases. No traces of SDF-1 were found in the vitreous samples of eight nondiabetic patients who were treated for other ailments.

With the hypothesis that SDF-1 is at the heart of the problem, scientists tested to see whether the addition of the protein would call stem cells and spur extraordinary blood vessel growth in the eyeballs of 10 laboratory mice. They succeeded, creating mice with retinopathy-like conditions. Then, as a treatment, scientists injected an SDF-1 antibody directly into the afflicted eyes. The antibody — which is simply another protein that binds to the SDF-1 — disabled SDF-1's ability to summon stem cells, effectively halting the growth of almost all new blood vessels, said Jason M. Butler, a graduate student in the Interdisciplinary Program in Biomedical Sciences and a member of the research team.

Scientists next want to test the technique in monkeys, and if it continues to be successful, to test the therapy in human clinical trials, said Scott, the senior author of the paper. The National Institutes of Health funded the research in mice.

"Brain" In A Dish Acts As Autopilot Living Computer

A University of Florida scientist has grown a living "brain" that can fly a simulated plane, giving scientists a novel way to observe how brain cells function as a network.

The "brain" — a collection of 25,000 living neurons, or nerve cells, taken from a rat's brain and cultured inside a glass dish — gives scientists a unique real-time window into the brain at the cellular level. By watching the brain cells interact, scientists hope to understand what causes neural disorders such as epilepsy and to determine noninvasive ways to intervene.

As living computers, they may someday be used to fly small unmanned airplanes or handle tasks that are dangerous for humans, such as search-and-rescue missions or bomb damage assessments.

"We're interested in studying how brains compute," said Thomas DeMarse, the UF assistant professor of biomedical engineering who designed the study. "If you think about your brain, and learning and the memory process, I can ask you questions about when you were 5 years old and you can retrieve information. That's a tremendous capacity for memory. In fact, you perform fairly simple tasks that you would think a computer would easily be able to accomplish, but in fact it can't."

While computers are very fast at processing some kinds of information, they can't approach the flexibility of the human brain, DeMarse said. In particular, brains can easily make certain kinds of computations — such as recognizing an unfamiliar piece of furniture as a table or a lamp — that are very difficult to program into today's computers.

"If we can extract the rules of how these neural networks are doing computations like pattern recognition, we can apply that to create novel computing systems," he said.
